Summary

Background We investigated a consecutive series of children with chronic enterocolitis and regressive developmental disorder.

Methods 12 children (mean age 6 years [range 3–10], 11 boys) were referred to a paediatric gastroenterology unit with a history of normal development followed by loss of acquired skills, including language, together with diarrhoea and abdominal pain. Children underwent gastroenterological, neurological, and developmental assessment and review of developmental records. Ileocolonoscopy and biopsy sampling, magnetic-resonance imaging (MRI), electroencephalography (EEG), and lumbar puncture were done under sedation. Barium follow-through radiography was done where possible. Biochemical, haematological, and immunological profiles were examined.

Findings Onset of behavioural symptoms was associated, by the parents, with measles, mumps, and rubella vaccination in eight of the 12 children, with measles infection in one child, and otitis media in another. All 12 children had intestinal abnormalities, ranging from lymphoid nodular hyperplasia to aphthoid ulceration. Histology showed patchy chronic inflammation in 11 children and reactive ileal lymphoid hyperplasia in seven, but no granulomas. Behavioural disorder included autism (nine), disintegrative disorders (one), and possible postviral or vaccinal encephalitis (two). There were no focal neurological abnormalities and MRI and EEG tests were normal. Abnormal laboratory results were significantly raised urinary methylmalonic acid compared with age-matched controls (p=0·003), low haemoglobin in four, and low serum IgA in four children.

Interpretation We identified associated gastrointestinal disease and developmental regression in a group of previously normal children, which was generally associated in time with possible environmental triggers.

Introduction

We saw several children who, after a period of apparent normality, lost acquired skills, including communication. They all had gastrointestinal symptoms, including abdominal pain, diarrhoea, and vomiting and, in some cases, food intolerance. We describe the clinical findings, and gastrointestinal features of these children.

Patients and methods

12 children, consecutively referred to the department of paediatric gastroenterology with a history of a pervasive developmental disorder with loss of acquired skills and intestinal symptoms (diarhoea, abdominal pain, bloating, and food intolerance), were investigated. All children were admitted to the ward for a week, accompanied by their parents.

Clinical investigations

We took histories, including details of immunisations and exposure to infectious diseases, and assessed the children. In 11 cases the history was obtained by the senior clinician (JW-S). Neurodevelopmental and psychiatric assessments were done by a consultant staff (PH, MB) with HMS-4 criteria. Developmental delays included a review of prospective developmental records from parents, health visitors, and general practitioners. Four children did not undergo psychiatric assessment in hospital; all had been assessed professionally elsewhere, so these assessments were used as the basis for their behavioural diagnosis.

After bowel preparation, ileocolonoscopy was performed by SHM or MAT under sedation with midazolam and pethidine. Paired frozen and formalin-fixed mucosal biopsy samples were taken from the terminal ileum; ascending, transverse, descending, and sigmoid colons, and from the rectum. The procedure was recorded by video or still images, and were compared with images of the previous seven consecutive paediatric colonoscopies (four normal colonoscopies and three on children with ulcerative colitis), in which the physician reported normal appearances in the terminal ileum. Barium follow-through radiography was possible in some cases.

Also under sedation, cerebral magnetic-resonance imaging (MRI), electroencephalography (EEG) including visual, brain stem auditory, and sensory evoked potentials (where compliance made these possible), and lumbar puncture were done.

Laboratory investigations

Thyroid function, serum long-chain fatty acids, and cerebrospinal-fluid lactate were measured to exclude known causes of childhood neurodegenerative disease. Urinary methylmalonic acid was measured in random urine samples from eight of the 12 children and 14 age-matched and sex-matched normal controls, by a modification of a technique described previously. Chromatograms were scanned digitally on computer, to analyse the methylmalonic-acid zones from cases and controls. Urinary methylmalonic-acid concentrations in patients and controls were compared by a two-sample t test. Urinary creatinine was estimated by routine spectrophotometric assay.

Children were screened for antidiomysial antibodies and boys were screened for fragile-X if this had not been done.
Histology
Formalin-fixed biopsy samples of ileum and colon were assessed by a pathologist (SED). Five ileocolonic biopsy series from age-matched and site-matched controls were compared. Histological reports showed histologically normal mucosa were obtained by consensus. All tissues were assessed by three other clinical and experimental pathologists (APD, AA, AJW).

Ethical approval and consent
Investigations were approved by the Ethical Practice Committee of the Royal Free Hospital NHS Trust and all parents gave informed consent.

Results
Clinical details of the children are shown in tables 1 and 2. None had neurological abnormalities on clinical examination; MRI scans, EEGs, and cerebrospinal-fluid profiles were normal; and fragile X was negative. Prospective developmental records showed satisfactory achievement of early milestones in all children. The only girl (child number eight) was noted to be a slow developer compared with her older sister. She was subsequently found to have coarctation of the aorta. The only girl (child number eight) was noted to be a slow developer compared with her older sister. She was subsequently found to be hypothyroid and was treated appropriately.

Table 2 summarises the neuropsychiatric diagnoses; the apparent precipitating events; onset of both behaviour and bowel symptoms.

Laboratory tests
All children were antiendomysial-antibody negative and common enteric pathogens were not identified by culture, microscopy, or serology. Urinary methylmalonic-acid excretion was significantly raised in all eight children who trained at an infant because behavioural features made children unable to communicate symptoms.

One child (child six) had received monovalent measles vaccine at 16 months, after which his development slowed (confirmed by professional assessors). No association was made with the vaccine at the time. He received a dose of measles, mumps, and rubella vaccine at age 4·5 years, the day after which his mother described a striking deterioration in his behaviour, which she did link with the immunisation. Child nine received measles, mumps, and rubella vaccine at 16 months. At 18 months he developed recurrent antibiotic-resistant otitis media and the first behavioural symptoms, including disinterest in his sibling and lack of play.

Figure 1: Urinary methylmalonic-acid excretion in patients and controls

p=Significance of mean excretion in patients compared with controls.
neutrophil infiltrate and granulomas were not present. within the tissue section (figure 3). There was no case, more than three expanded and confluent lymphoid was present in the ileal biopsies of seven children. In each whose images were available for comparison.

Terminal ileum (figure 2) was seen in the seven children endoscopy. The normal endoscopic appearance of the other child in whom the ileum was not reached at (figure 2), and identified by barium follow-through in one the terminal ileum which was seen in nine children consistent feature was lymphoid nodular hyperplasia of colon

Histological findings are summarised in table 1. Macroscopic colonic appearances were reported as normal in four children. The remaining eight had colonic and rectal mucosal abnormalities including granularity, loss of vascular pattern, patchy erythema, lymphoid nodular hyperplasia, and in two cases, aphthoid ulceration. Four cases showed the “red halo” sign, a round swollen caecal lymphoid follicles, an early endoscopic feature of Crohn’s disease. 3 The most striking and swollen caecal lymphoid follicles in the vicinity of mononuclear-cell infiltrates was the presence of reactive germinal centres with reactive changes in the intestinal pathological changes and the fact that previous studies have found intestinal dysfunction in children with developmental disorders. Intestinal and behavioural pathologies may have occurred together by chance, reflecting a selection bias in a self-referred group; however, the uniformity of the intestinal pathological changes and the fact that previous studies have found intestinal dysfunction in children with autistic-spectrum disorders, suggests that the connection is real and reflects a unique disease process. Asperger first recorded the link between coeliac disease and behavioural psychoses. 4 Walker-Smith and colleagues 24% of a group of autistic children with no showed enlarged terminal cells, with reactive changes that included an excess of tingible body macrophages.

There was no clear correlation between the endoscopic appearances and the histological findings; chronic inflammatory changes were apparent histologically in endoscopically normal areas of the colon. In five cases there was focal acute inflammation with infiltration of the lamina propria by neutrophils; in three of these, neutrophils infiltrated the caecal (figure 3) and rectal epithelium. There were no crypt abscesses. Occasional bifid crypts were noted but overall crypt architecture was normal. There was no goblet-cell depletion but occasional collections of eosinophils were seen in the mucosa. There were no granulomata. Parasites and organisms were not seen. None of the changes described above were seen in any of the normal biopsy specimens.

### Discussion

We describe a pattern of colitis and ileal-lymphoid-nodular hyperplasia in children with developmental disorders. Intestinal and behavioural pathologies may have occurred together by chance, reflecting a selection bias in a self-referred group; however, the uniformity of the intestinal pathological changes and the fact that previous studies have found intestinal dysfunction in children with autistic-spectrum disorders, suggests that the connection is real and reflects a unique disease process.

were tested, compared with age-matched controls (p=0.003; figure 1). Abnormal laboratory tests are shown in table 1.

### Endoscopic findings

The caecum was seen in all cases, and the ileum in all but two cases. Endoscopic findings are shown in table 1. Macroporphic colonoscopic appearances were reported as normal in four children. The remaining eight had colonic and rectal mucosal abnormalities including granularity, growth of vascular pattern, patchy erythema, lymphoid nodular hyperplasia, and in two cases, aphthoid ulceration. Four cases showed the “red halo” sign, a round swollen caecal lymphoid follicles, an early endoscopic feature of Crohn’s disease. 3 The most striking and swollen caecal lymphoid follicles in the vicinity of mononuclear-cell infiltrates was the presence of reactive germinal centres with reactive changes in the intestinal pathological changes and the fact that previous studies have found intestinal dysfunction in children with developmental disorders. Intestinal and behavioural pathologies may have occurred together by chance, reflecting a selection bias in a self-referred group; however, the uniformity of the intestinal pathological changes and the fact that previous studies have found intestinal dysfunction in children with autistic-spectrum disorders, suggests that the connection is real and reflects a unique disease process.
The “opioid excess” theory of autism, put forward first by Panksepp and colleagues,7 later by Reichelt and colleagues,8 and Shattock and colleagues,9 proposes that autistic disorders result from incomplete breakdown and excessive absorption of gut-derived peptides from foods, including barley, rye, oats, and casein from milk and dairy products. These peptides may exert central-opioid effects indirectly, through the formation of ligands with peptidase enzymes required for breakdown of endogenous central-nervous-system opioids,9 leading to disruption of normal neuroregulation and brain development by endogenous encephalins and endorphins.

One aspect of impaired intestinal function that could permit increased permeability to exogenous peptides is deficiency of the phenyl-sulphur-transferase systems, as described by Waring.10 The normally sulphated glycoprotein matrix of the gut wall acts to regulate cell and molecular trafficking.11 Disruption of this matrix and increased intestinal permeability, both features of inflammatory bowel disease,12 may cause both intestinal and neuropsychiatric dysfunction. Impaired enterohepatic sulphation and consequent detoxification of compounds such as the phenolic amines (dopamine, tyramine, and serotonin)13 may also contribute. Both the presence of intestinal inflammation and absence of detectable neurological abnormality in our children are consistent with an exogenous influence upon cerebral function. Lucarelli’s observation that after removal of a provocative enteric antigen children achieved symptomatic behavioural improvement, suggests a reversible element in this condition.13

Despite consistent gastrointestinal findings, behavioural changes in these children were more heterogeneous. In some cases the onset and course of developmental regression was precipitous, with children losing all communication skills over a few weeks to months. This regression is consistent with a disintegrative psychosis (Heller’s disease), which typically occurs when normally developing children show striking behaviour changes and developmental regression, commonly in association with some loss of coordination and bowel or bladder function.14 Disintegrative psychosis is typically described as occurring in children after at least 2–3 years of apparently normal development.

Disintegrative psychosis is recognised as a sequel to measles encephalitis, although in most cases no cause is ever identified.14 Viral encephalitis can give rise to autistic disorders, particularly when it occurs early in life.15 Rubella virus is associated with autism and the combined measles, mumps, and rubella vaccine (rather than monovalent measles vaccine) has also been implicated. Fudenberg16 noted that for 15 of 20 autistic children, the first symptoms developed within a week of vaccination. Gupta17 commented on the striking association between measles, mumps, and rubella vaccination and the onset of behavioural symptoms in all the children that he had investigated for regressive autism. Measles virus18,19 and measles vaccination20 have both been implicated as risk
factors for Crohn’s disease and persistent measles vaccine-strain virus infection has been found in children with autoimmune hepatitis.10,11

We did not prove an association between measles, mumps, and rubella virus and the syndrome described. Virological studies are underway that may help to resolve this issue.

If there is a causal link between measles, mumps, and rubella virus and this syndrome, a rising incidence might be anticipated after the introduction of this vaccine in the UK in 1988. Published evidence is inadequate to show whether there is a change in incidence12 or a link with measles, mumps, and rubella vaccine.13 A genetic predisposition to autistic-spectrum disorders is suggested by over-representation in boys and a greater concordance rate in monozygotic than in dizygotic twins.14 In the context of susceptibility to infection, a genetic association with autism, linked to a null allele of the complement (C) 4B gene located in the class III region of the major-histocompatibility complex, has been recorded by Warren and colleagues.15 C4B-gene products are crucial for the activation of the complement pathway and protection against infection: individuals inheriting one or two C4B null alleles may not handle certain viruses appropriately, possibly including attenuated strains.

Urinary methylmalonic-acid concentrations were raised in most of the children, a finding indicative of a functional vitamin B12 deficiency. Although vitamin B12 concentrations were normal, serum B12 is not a good measure of functional B12 status.16 Urinary methylmalonic-acid excretion is increased in disorders such as Crohn’s disease, in which cobalamin excretion is not reabsorbed. A similar problem may have occurred in the children in our study. Vitamin B12 is essential for myelinogenesis in the developing central nervous system, a process that is not complete until around the age of 10 years. B12 deficiency may, therefore, be a contributory factor in the developmental regression.17

We have identified a chronic enteropathy in children that may be related to neurotrophic dysregulation. In most cases, onset of symptoms was after measles, mumps, and rubella immunisation; further investigations are needed to examine this syndrome and its possible relation to this vaccine.

Addendum:
Up to Jan 28, a further 40 patients have been assessed; 39 with the syndrome.
